Abstract—After working for some time, developers commit their code changes to a version control system. When doing so, research shows that they often bundle unrelated changes (e.g., bug fix and refactoring) in a single commit, thus creating a so-called tangled commit. Sharing tangled commits is problematic because it makes review, reversion, and integration of these commits harder and historical analyses of the project less reliable.

Researchers have worked at untangling existing commits, i.e., finding which part of a commit relates to which task. In this paper, we contribute to this line of work in two ways: (1) A publicly available dataset of untangled code changes, created with the help of two developers who accurately split their code changes into self contained tasks over a period of four months; (2) based on this dataset we devise and assess EpiceaUntangler, an approach to help developers share untangled commits (aka. atomic commits) by using fine-grained code change information. We further evaluate EpiceaUntangler by deploying it to 7 developers, who used it for 2 weeks. We recorded a median success rate of 91% and average one of 75%, in automatically creating clusters of untangled fine-grained code changes.

I. INTRODUCTION

Version Control Systems (VCS), such as Git and Subversion, allow programmers to control changes to source code, in a way that they make it possible to find who made each software change, when, and where. This information is important to support both the coordination of developers working in teams [1] and the creation of many recommendation and prediction systems related to software quality [2].

Research shows that developers often bundle unrelated changes (e.g., bug fix and refactoring) in a single commit [3], creating a so-called tangled commit, such as the following:

```java
--- src/java/main/org/jaxen/expr/AdditiveExpr.java (revision 1251)
+++ src/java/main/org/jaxen/expr/AdditiveExpr.java (revision 1252)
@@ -61,7 +61,7 @@
  */public interface AdditiveExpr extends BinaryExpr

The tangled commit above contains both a refactoring (the move of 'getOperator()' to a different place, not shown in this extract), and code formatting (the move of an interface definition to its own line). Sharing tangled commits is problematic because it makes code review, reversion, and integration harder and historical analyses of the project less reliable [4]. For example, even the integration of the code formatting change included in the commit above would be a demanding task.

Researchers have worked on untangling existing commits, i.e., finding how to separate parts of a commit relating to different tasks. Herzig and Zeller presented the earliest and most significant results in this area [3]: They implemented the first algorithm that can automatically untangle commits given artificially tangled ones.

In this paper, we expand on this previous work by: (1) Working in an untyped setting where most of the approach by Herzig and Zeller is inapplicable; (2) considering fine-grained code change information gathered during development (e.g., time at which each line has changed and all versions of each line); and (3) evaluating the resulting approach both on data generated by programmers who manually label it, and with programmers working on real-world development tasks.

The ultimate goal of our work is to help developers of dynamically-typed code share untangled commits. To that end, we: (1) asked 7 developers to manually cluster changes for each of their commits using a dedicated tool, for a period of 4 months; (2) manually validated the generated data, selecting the data recorded by 2 of these developers, and computed a number of features based on the their fine-grained code changes; (3) modeled the problem of predicting whether two fine-grained changes belong together using a variety of machine learning approaches, determined the most appropriate one and then identified the most significant features; (4) designed an algorithm that uses the machine learner result to propose an automatic clustering of any tangled commit and developed a corresponding tool, EpiceaUntangler; and finally (5) evaluated the effectiveness of our approach with developers who used EpiceaUntangler in their daily work for two weeks.

Our results show that three features are especially important to perform clustering of fine-grained code changes: the time and the ordered distance between the changes, and whether the changed code belongs to the same class. By modeling these features with Random Forests [5], we identify whether two changes belong to the same commit with an accuracy of 95%, if training and testing on the same developer, and more than 88% if tested on a different developer. A set of 200 manually clustered fine-grained code changes (i.e., the equivalent of a few days of work) was sufficient to reach good performances. When deploying EpiceaUntangler with new developers during their daily tasks, we recorded an average success rate of 75% and a median one of 91%.

1from Jaxen (http://jaxen.codehaus.org), commit: svn-1252, 2006-11-09
When developers want to share their work in a VCS, they will, more often than not, realize that they have done more than one activity, e.g., fixed a bug, reformatted a method, and fixed a typo in a comment. Sharing everything in a single tangled commit is regarded as bad practice because it makes the following activities more difficult:

- **Review:** reviewers have to understand the code changes of all the activities at once [6]–[8];
- **Reversion:** developers have to revert all changes of a problematic commit even when only one part of the commit is problematic [1];
- **Integration:** integrators have to integrate or reject whole commits, e.g., they cannot accept a code formatting operation and reject a bug fix included in the same commit [9];
- **Historical analysis:** researchers need to associate activities to files to conduct statistical analyses while, e.g., mining software repositories [4].

A. Existing Solutions for Tangled Changes

To avoid tangled commits, developers could organize their work so that, at commit time, only one activity’s code is to be shared. This requires frequent commits and interruptions in the developer’s work flow [10]–[13]. Even with a lot of discipline, there will be times when a developer will have to split changed code into several commits.

To separate code from several activities into different commits, some tools (e.g., ‘git add’) let the user selects which files and lines to commit first. Being line based, these tools share the following problems: (1) The code present at commit time might be incomplete [14]: Each change to a line shadows previous changes of the same line making it impossible to commit the line as it was before the last change; (2) a commit resulting of a manual selection of a subset of all changed lines might be invalid: e.g., a developer might commit the beginning of a function definition but not the end; and (3) changed lines are shown in the order they appear in their files irrespective of their modification time: This makes it difficult for developers to select lines changed closely in time.

A great source of inspiration for us comes from Herzig et al., [3], [4], who implemented an algorithm to automatically untangle commits. Their algorithm uses several confidence voters to decide whether two lines of a tangled commit should be put in the same cluster. They aggregate the results of each confidence voters into a single score, and then use the concepts of a multilevel graph-partitioning algorithm by Karypis and Kumar [15] to generate the clusters. Their voters include:

- ‘FileDistance’: the number of lines between the two lines if they are both in the same file;
- ‘PackageDistance’: the relationship between the packages each line was changed into;
- ‘CallGraph’: the difference between the call graphs of the program with each line change applied separately;
- ‘ChangeCouplings’: the frequency with which the files both lines were changed into are committed together, using the work from Zimmermann et al., [2];
- ‘DataDependency’: a boolean indicating if the two lines read or write the same variable(s).

We see the following limitations to Herzig et al., work that we address in the current paper:

- **Dependence on static-analysis:** The ‘CallGraph’ and ‘DataDependency’ voters rely on static analyses that might not be possible for dynamically-typed programming languages (or that might be available in a weaker form);
- **Incomplete:** The tangled commits used as input to the algorithm suffer from the incompleteness problem described earlier in this section: If a line is changed twice before a commit, the commit only contains the latest version of the line, shadowing a previous version of the line which could have been part of an untangled commit;
- **Artificiality:** The validation by Herzig et al., relies on a classification by themselves of 7,000 existing commits without feedback from each project’s experts. We believe that only the author of each commit can, at commit time, best organize his changes into untangled commits. Moreover, Herzig et al., untangling algorithm relies on the knowledge of the expected number of untangled commits for a particular tangled one. With the goal of helping developers creating untangled commits, we do not have access to this knowledge.

In this paper, we propose to alleviate the problems of the Herzig et al., approach by (a) expanding it to a dynamically-typed environment where some kinds of analyses are not available; (b) using fine-grained changes collected during development sessions; (c) relying on developer-approved data for the validation of our approach. Following are the requirements of our approach:

(a) **The Dynamically-Typed Setting:** Whereas the Herzig et al., approach relies on static analysis of Java programs to untangle commits, our approach must help developers create untangled commits in a dynamically-typed environment. Certain types of static analysis, e.g. accurate call graph analysis, is not possible for dynamically-typed languages. Therefore, our approach should not rely on static analysis.

(b) **Fine-Grained Changes:** In modern integrated development environments (IDEs), tools can be notified each time a method is changed. As a result, a tool could listen to all fine-grained changes made by developers and, at commit time, present the developer a list of all the changes they have done. For example, a developer saving a method’s source code 3 times will result in 3 fine-grained changes. This is in contrast with most tools that only present the latest version of each changed line; this requirement tackles the incompleteness limitation.

(c) **Developer-Approved Data:** The untangling algorithm should be based on data from manually untangled commits by developers who created the tangled commits. As a result, a tool could use the data from manually untangled commits to help developers create untangled commits. The final version of the approach should present each developer, at commit time, a list of the automatically found untangled commits with their fine-grained changes. Each developer could then reorganize these automatically-computed clusters of changes. Results must be validated by comparing the automatically-computed clusters of changes against the manual reorganization of the developer.
Fig. 1. IDE events recorded by Epicea; dashed ones are not considered.

III. PROPOSED SOLUTION

In a nutshell, our solution is to develop an approach and associated tools to help developers share untangled commits. The tools log all the fine-grained changes made by developers as they change the source code. When a developer wants to commit her changes, the tool, based on an analysis of the recorded information, presents several automatically-computed clusters of changes: Each cluster represents a distinct activity of the developer since last commit. The developer may then add a comment to each cluster and, if necessary, adapt the automatic clustering (by adding/removing clusters and moving changes to different clusters). Once the developer validates the clusters, the tool generates a commit per cluster and publishes them to a repository. In the following section, we present our solution decomposed in individual parts.

A. Epicea: Event modeler with fine-grained changes

Central to our approach is the collection of fine-grained information. To conduct this task, we use Epicea [16], a tool we developed to model IDE events. In essence, Epicea listens to actions taking place in the IDE and records different types of events. A simplified version of the events recorded by Epicea is shown in Figure 1. Epicea records complete information of these events (e.g., whether a test run failed), including timestamp. As previous studies (both in Eclipse [17] and in Smalltalk [18]) showed that save-based recording produces reliable fine-grained code change data, we record code change operations (add, modify, and delete classes and methods) every time the user saves the code. Epicea stores the collected data as a sequence of serialized objects into plain text files.

B. Voters

Once the data is collected, we have to characterize it in a way that it can be used for generating untangled changes. Similarly to Herzig et al., in [3], [4], the first step is to model our clustering task into a binary classification problem: For all the potential pairs of recorded fine-grained changes, we want to determine whether they belong in the same cluster. To this end, we implement a number of features or, maintaining the term used by Herzig et al., [3], voters, which describe different relations between the considered changes. Our voters (detailed in Table I) span the following six dimensions:

1) Code structure: Although non-typed languages do not allow for deep static analysis, it is possible to compute basic relations. Our three voters in this dimension consider whether the two changes happen in the same package, class, and/or method.
2) Content: This voter analyzes the output of the methods before and after the changes, and returns true in case the output remained the same but basic formatting properties changed. This voter should help linking changes regarding refactoring actions.
3) Testing: Epicea records test runs. The rationale of this voter is that two changes happening between a run of the same test could be related to the same task (e.g., this should hold in the case of test-driven development).
4) Spread: These voters measure the distance between the two considered changes, considering time passed and number of other changes in between. We expect close changes to be more related.
5) Message sending: This dimension analyzes whether the changes involve message sending (also known as ‘method invocations’), in languages such as Java or C# that are possibly related.
6) Variable accessing: This dimension computes relations between the variable accessed by the two changes: For example, a change that adds a new instance variable may be related to a change that adds an usage of the same variable in a method.

The input of each voter is a pair of changes, and the output is of the type specified in column ‘Type’ of Table I.

C. Machine learning approaches

Our approach computes the values for each voter per each pair of changes (for performance reasons, we only consider fine-grained change pairs that are less than 3 days apart); to aggregate these values and train models that would predict whether the two changes should be in the same cluster, we use machine learning (ML).

We consider three well-known machine learning algorithms [19]: (1) binary logistic regression (’binlogreg’), (2) Naive bayes (’naivebayes’), and (3) random forests [5] (’ranforest’). We chose these algorithms not only because they have been applied successfully to a number of data mining tasks related to software engineering, but also because they make quite different assumptions on the underlying data and model (e.g., ‘naivebayes’ relies on the conditional independence assumption, i.e., the value of a voter is unrelated to the value of the others, and ‘binlogreg’ requires each observation to be independent and linearity of independent variables and log odds), thus they can offer different interpretations. The choice of the most appropriate machine learning algorithm is based on the empirical data collected during the experiment.

This machine learning step takes as an input the values computed by the voters, and it outputs a probability that the two changes belong to the same cluster.

D. Clustering

The last necessary step in our approach is to take the output of the machine learning step, computed on each pair...

### Table 1. Different voters tested in our investigation.

<table>

<td>They start or stop accessing a number of the same variable names.</td>
</tr>
</tbody>
</table>

The output of this step is the set of independent clusters of fine-grained changes, which is eventually displayed to the user with a dedicated user interface.

### IV. Research Method

In this section, we describe how we structure our research in terms of research questions, we present the research settings, and we outline our research method.

#### A. Research questions

The goal of our work is to devise and test the approach we previously described to untangle code changes at a fine level of granularity. Accordingly, we structure our investigation through the following research questions:

**RQ1:** Which voters are significant to untangle fine-grained code changes?

With this question we aim to understand which are the most important voters in our untyped setting. To answer this research question, we consider the machine learning task of deciding whether two changes should belong to the same cluster. In doing so, we also determine which machine learning approach among the three we test, is better suited to model the problem through our voters.

**RQ2:** How effective is a machine learning model based on the significant voters in untangling historical fine-grained code changes?

Once we find the most significant voters and the best machine learning approach, we are interested to know their performance in predicting whether two changes should belong to the same cluster. We also want to investigate the effect asserted by individual developers’ working styles on prediction performance; for this we train and test the machine learner on data generated by different developers (e.g., training on one developer’s data and testing on another developer’s data).

**RQ3:** How effective is a tool based on the best voters and machine learning approach, when deployed with developers working on their daily tasks?

Finally, we want to devise an approach EpiceaUntangler, based on the best machine learner and voters, that would be able to generate clusters and present them with a graphical user interface. We want to test its effectiveness when deployed with participants having two features: (1) Their data should not have been used for training the classifier, and (2) they should be working on their daily working tasks as usual.

#### B. Research settings

Our study took place with professional developers, researchers, and students using the Pharo environment. Pharo is an open-source dialect of Smalltalk and implementation of its programming environment. It was forked from Squeak in 2008 and it is rapidly evolving. Currently, Pharo has around 60 worldwide contributors, it is used by more than 15 universities to teach programming and by 10 research groups to build research tools, and more than 50 companies are deploying Pharo applications in production daily.

We chose Pharo as a case study for two main reasons: (1) The Pharo open-source community of developers has been open, since its inception, to welcome and thoroughly evaluate research tools (e.g., [20]–[22]); and (2) the programming language, the development environment, and the versioning system are tightly integrated. The later feature allowed a faster prototyping of an approach to record fine-grained code changes and interaction with testing and the versioning system. The former feature allowed us to collect fine-grained data about

2http://pharo.org/
code changes and IDE interactions from participants doing real-world development work, and it enabled us to deploy our resulting tool with more participants and evaluate the results. Moreover, many research tools tested within Pharo later became integral part of the environment (e.g., [23]); it is our interest not only to improve the state of the art in untangling code changes, but also creating an approach that can be used in real-world scenarios.

C. Research steps

1) Fine-grained data generation and collection: To answer our first two research questions, we need a ground truth to train and test our voters and machine learning approaches. Such a ground truth should be a reliable dataset containing fine-grained code changes correctly split into tasks by their authors. To obtain this, we contacted 7 participants actively contributing to Pharo, including the first author of this paper. We asked them to install Epicea and to use the tool (i.e., Epicea Task Clusterer (ETC), Figure 2) that we devised to manually cluster their fine-grained code changes. We showed a screencast3 denoing the tool to all the participants before they started using it, so that they could understand the goal of the experiment and adapt their workflow accordingly. Every time participants decided to commit their source code to the versioning system, during their normal work, the ETC’s interface would appear (as in Figure 2) displaying a list of all the fine-grained changes, since the previous commit, that the user had to manually cluster into the expected tasks.

<table>
<thead>
<tr>
<th>P_ID</th>

<td>48</td>
<td>36</td>
</tr>
</tbody>
</table>

In detail, the main user interface of Epicea Task Clusterer (shown in Figure 2) works as in the following: In the top pane, each column (e.g., Point 1) represents a task (to group an activity of the user), and each item in a column represents a code change (e.g., Point 2). Each code change is in a ClassName+methodName format, and the icon shows the type of change (as in Figure 1). The bottom pane (Point 3) shows the details of the selected change, in a unified-diff format. The user can review the listed changes and perform three actions to specify the expected clustering for them: Add a new empty task/cluster (Point 4), reopen an already closed task/cluster (Point 5), and move changes between columns (with drag and drop, Point 6). Once the clustering task is completed, the user presses the button ‘Done’, and the interface disappears.

2) Data analysis and evaluation of voters: Once the participants concluded the data collection period of 4 months, we conducted exploratory data analysis [24] on the generated clustered changes. We found that the data generated by five users was extremely sparse and inconsistent; these users confirmed this and explained that they were not able to reliably generate the necessary data, mostly because of time issues arisen during the experiment period. We removed this data, and kept the data generated from the remaining two users (including the first author of this paper) whose features are described in the top half of Table II. The resulting dataset, which we name 2devs, is described in Table III.

<table>

</tr>
</tbody>
</table>

Using 2devs we answered RQ1 and RQ2. As previously detailed (see Section III-C), we used machine learning to automatically identify pairs of changes belonging to the same commit, by modeling it as a binary classification problem. For all potential pairs of changes in the 2devs dataset, we calculated values for all the voters in Table I and labeled with ‘true’ if the changes belonged to the same commit or ‘false’ otherwise. As our dataset was unbalanced (the false class overruled the true class by a ratio of 4:1), adjustments where necessary to avoid overfitting. Models where thus trained with a ratio of 2:1 samples for the false and true class respectively.

Evaluation of voters. To evaluate each trained model, we used standard machine learning metrics [19], such as precision (prec), recall (rec), accuracy (acc), the Area Under the receiver operating characteristic Curve (auc) and the F-measure (f.measure). Models where trained with an increasing number of samples as input (10^4 to 10^6 samples), in order to determine the minimum number of samples required to obtain adequate performance. At each input size, we used random selection 10-fold cross validation to evaluate model stability and reported results based on the mean of the 10 runs. We selected the best classifier and applied a classifier-
specific process to rank voters according to their importance in the classification process. Then we incrementally trimmed the voter set starting from the least important feature until the performance of the classifier was severely impacted. Finally, we retrained the best classified with the trimmed voter set and used as our final prediction model. The final model was then exposed as a web service that EpiceaUntangler used to drive the change untangling process to answer RQ3.

3) Deployment and evaluation with developers: Once we completed the creation and evaluation of the best ML approach and features on dataset 2devs, and obtained promising results, we created the corresponding implementation in EpiceaUntangler, a tool that developers can use in real-world development.

Our approach records all the fine-grained information, exactly as done for the data collection phase. Then, when a developer wants to commit, it computes the values for all the significant voters for each pair of code changes, and queries the web service implementing the final model of the ML classifier. For each change-pair, the web service returns a score between 0 and 1, indicating the probability that the two changes belong to the same cluster, according to the trained model. EpiceaUntangler aggregates all the scores to form clusters; this index is defined as using the following formula:

\[ J_{C_i,E_j} = \frac{|C_i \cap E_j|}{|C_i \cup E_j|} \]

This Jaccard index represents how much two sets coincide. It ranges from 0 to 1, where 1 means the two sets are equal (e.g., C3 and E1 in Figure 4) and 0 means the two sets have nothing in common (e.g., C4 and E2 in Figure 4).

From the resulting matrix we want to know which computed cluster matches which expected cluster. This can be obtained by maximizing the sum of the Jaccard indexes over all permutations. For the sample in Figure 4 the maximum sum \( \sum_{i,j} J_{C_i,E_j} \) is attained for this set of pairs:

\( \text{Matching} = \{(C1, E2), (C2, E4), (C3, E1), (C4, E3), (C5, E5)\} \)

We compute the success rate of our algorithm using the following formula:

\[ \text{SuccessRate} = \frac{\#\text{SuccessfullyClusteredChanges}}{\#\text{Changes}} \]

A change \( ch_i \) is successfully clustered if the computed and expected clusters that contain \( ch_i \) are in the same pair of the Matching set. In Figure 4, all changes are successfully clustered except \( ch6 \). This gives us a success rate of \( \frac{5}{6} = 0.83 \).
V. Results

In this section we answer our research questions, by describing the results we obtained in our evaluations.

A. What are the dominant and significant voters?

As a first step to answer our first research question, we use all the machine learning approaches we consider on the collected data and we evaluate whether an approach performs undoubtedly better. Table IV reports the results of the classification performance of each machine learning approach for predicting whether two changes belong together, using a training size of $n = 320,000$ pairs (or 800 fine-grained changes), on the 2devs dataset. Overall, and across all metrics, the Random Forests algorithm delivers the best results, by a big margin. The high REC measurement of the ‘binlogreg’ result can be justified by its equally low PREC; the classifier marks most of the file changes as belonging in the same cluster, but few of those decisions are correct.

<table>
<thead>
<tr>
<th>Classifier</th>
<th>AUC</th>
<th>ACC</th>
<th>PREC</th>
<th>REC</th>
<th>F.MEASURE</th>

<td>0.88</td>
<td>0.90</td>
</tr>
</tbody>
</table>

Once we established that ‘ranforest’ delivers the best results, we assessed the importance of each voter for its classification result. We used the process suggested by Genuer et al., [25]. Specifically, we run the algorithm 50 times on a randomly selected sample of $10^6$ change pairs, using a large number of generated trees (500) and trying 5 random variables per split. Then, we used the mean across 50 runs of the Mean Decrease in Accuracy metric, as reported by the R implementation of the ranforest algorithm, to evaluate the importance of each feature. The results can be seen in Figure 5. The three most important voters are: (1) the time difference between the changes, (2) the ordered distance of the changes, (3) and whether the changed code belonged in the same class. We cannot make inferences about whether the effect of each voter is positive or negative to the response class; nevertheless, we believe that the results are indicative of the task-based nature of software development.

B. How effective is random forests using the dominant voters?

We answer our second research question by using only the three most important voters to train the prediction model. The prediction results are reported in Table IV, marked as ‘ranforest-trimmed’. We see that even with just those voters we obtain very good prediction results: The new model is within 3% of the performance of the model trained in all metrics.

Furthermore, we analyze the impact of the developer who made the changes on training and testing. We expect that behaviors of developers might be different and have a significant impact on the model.

We start showing that we obtain the best results when we train and test from data generated by the same developer (the ‘intradev’ dataset in Figure 6). This confirms our hypothesis that the behavior of the specific developer has an impact on the model and the results. Furthermore, we see that the results are not equally good when training with data from one developer and testing on the other (the ‘crossdev’ dataset); moreover we see that as we increase the training size, there is a drop in performances. This can be attributed to overfitting the model to the working habits of each individual developer. Finally, we see that we can train accurate models by combining data from
multiple developers. In the ‘combined’ dataset, we combine the data generated by both developers and use this to train the model; this means that training and testing data is taken from both samples. Figure 6 shows that this dataset reaches high and stable results; and overfitting seems not present.

What is interesting to note is that the number of fine-grained changes required for training in both the combined and intradev cases is low: with 200 changes we can obtain prediction results only 2% worse (in terms of acc) on average than if we train with 800 changes. As 200 fine-grained changes are the equivalent of a few days of work,\(^4\) we have encouraging evidence that an accurate model can be trained fast and deliver good results for a single developer. Moreover, a pre-trained model with data from multiple developers might be enough as a starting point for an untangling tool, which could then be trained to a particular developer’s working habits.

Overall, the results show that using the random forest algorithm, a randomized set of about 200 fine-grained changes and a few easy to calculate voters, we can train a prediction model that can identify whether two changes belong in the same commit with an accuracy of 95% for a single developer.

C. How effective is EpiceaUntangler when used by developers?

We answered research question three by deploying EpiceaUntangler with developers and recording whether the clustering that it proposes corresponds to participants’ expectations. The dataset devEval, resulting from this evaluation is described in Table V. We notice that not all the developers worked full time on coding during the two weeks, thus producing less changes.

We compared each cluster we proposed to the cluster that the participant eventually judged as correct to be committed. The box plot in Figure 7 shows the obtained results: We observed a median\(^5\) success rate of 0.915 and an average of 0.753 with a standard deviation of 0.30.

We asked developers their opinion on the tool and received diverse feedback. Most developers were positive [P3, P4, P6, P8], \(\text{e.g.},\) P3 expressed the feeling that “EpiceaUntangler guesses correctly the clusters of changes, also in a big commit were I had 10 different clusters,” and P4 reported: “It works good in many cases, especially for not so big change sets.” At the same time, most developers [P4, P5, P6, P8] expressed concerns with the large amount of fine-grained information to be processed; they explained that it adds too much noise to see not only the last state of a method but also all the intermediate modifications to it, especially when belonging to

\(^4\)From the data we recorded, 200 fine-grained code changes correspond to two to five days of work, depending on the developer’s style and pace.

\(^5\)The results are not normally distributed, thus we report the median value.

We were surprised by the low impact of many of the voters in the untangling task: We deemed message sending and variable access, as well as testing information, to contribute more. Since our initial data analysis was conducted with changes collected by only two developers, a further study with a larger set of developers for generating training data would be useful to confirm or alter this result.

In the second research question, we asked how effective is the best performing machine learning algorithm (\text{i.e.}, random forests) when used with the most significant voters. The results were overall very good. Expectedly, we achieved the best results when training and testing on data from the same developer, nevertheless cross-developers results are promising and merged-developers results do not show overfitting; in addition, approximately 200 fine-grained code changes were enough to reach most of the effectiveness. This implies that training on more developers is necessary to achieve a more

\end{figure}

the same cluster. In the words of P8: “It was a bit painful to check everything.”

Some participants suggested improvements to the user interface: For example, P7 said that he “would like to option to delete tasks in the UI,” and P6 said: “I would like to type a name for each task in the UI, as a reminder while I cluster.”

VI. Discussion

In this section we discuss our results and show how we mitigated the threats that endanger them.

A. Results

In the first research question, we asked which voters, or features, are significant to untangle fine-grained code changes. Despite we implemented voters along six dimensions, only two dimensions were significant and contributed to most of the outcome: code structure and spread. In particular, the latter dimension has the greatest impact, by a big margin; while the only significant voter in the former dimension measured whether the two changes were happening in the same class. This implies that these voters can be applied to other object-oriented programming languages regardless of whether they use types or not. This is a ripe opportunity for testing the approach with different languages and in different settings. Moreover, although we have no information about the significance of the voters implemented by Herzig et al., [3], [4], studies can be designed and carried out to determine if and how untangling effectiveness increases as a result of combining their voters with our significant ones.

We were surprised by the low impact of many of the voters in the untangling task: We deemed message sending and variable access, as well as testing information, to contribute more. Since our initial data analysis was conducted with changes collected by only two developers, a further study with a larger set of developers for generating training data would be useful to confirm or alter this result.

In the second research question, we asked how effective is the best performing machine learning algorithm (\text{i.e.}, random forests) when used with the most significant voters. The results were overall very good. Expectedly, we achieved the best results when training and testing on data from the same developer, nevertheless cross-developers results are promising and merged-developers results do not show overfitting; in addition, approximately 200 fine-grained code changes were enough to reach most of the effectiveness. This implies that training on more developers is necessary to achieve a more
general approach, and there seem to be no risk of overfitting by doing it. Moreover, ideally every user should train the approach on her own programming behavior; this seems reasonable since the training can be effective with as little as a few days of work.

In the third research question, we investigate the effectiveness of the whole approach when deployed with programmers. Considering that the recruited participants were not used for training phase, results are in line with the effectiveness measured for RQ2. One of the most recurring complaints regarded the large number of changes to be verified and sorted at every commit. This is due to the fact that we showed all the fine-grained changes recorded, thus also intermediate states for the same change (when the developer saved multiple times). We expect this information overload problem to be mitigated once the approach is stable enough to work correctly in most cases. Nevertheless, we see a good opportunity for further investigating how certain fine-grained code changes can be omitted, without losing relevant information that would lead to the incompleteness discussed in Section II-A. Moreover, valuable comments regarded the UI of EpiceaUntangler. The UI evaluation goes beyond the scope of this paper, but improving the UI can be a fertile ground to have an impact on reducing the information overload of fine-grained code changes.

B. Threats to validity

Internal Validity. Our models and feature selection process are based on a dataset generated through the actions of two developers. While we have combined the actions of the developers and shown that they provide very good prediction performance and the evaluation of the EpiceaUntangler has been overwhelmingly positive, it is possible that our findings are biased towards the two developers’ working habits.

Bias with respect to developer working habits might also occur in our selection of evaluation subjects. To reduce this risk, we selected diverse developers, all of them working in different projects and even in different physical locations. Thus, we believe the participants represent a heterogeneous enough population of Pharo developers.

Construct Validity. The notion of task is ambiguous. In particular, each participant can interpret the task granularity differently. For example, consider a single bug fix which intended to fix two broken features. The participant could consider the changes either as two individual tasks, or everything as a single bug-fixing task. For mitigating this risk, we prepared a screencast with an example for users trying to establish a common criterion for task granularity. Moreover, we kept close contact with users for answering any doubt. However, this ambiguity in the definition of task does not reduce the precision of our success metric for answering RQ3 (SuccessRate), since it represents each user expectation: it compares EpiceaUntangler’s clustering with participant’s expected clustering.

The clustering computed by EpiceaUntangler may have influenced participants. When users had to evaluate the computed clustering (as shown in Figure 2), the initial clustering might have biased their answers.

External Validity. We used a specific platform (Pharo) and language environment (Smalltalk) to facilitate our study. A specific language may dictate a specific working style. For example, in a typed language setting, an IDE would immediately mark as erroneous cases where a type signature has changed and not all uses have been adapted, therefore prompting the developer to fix such cases. Therefore our results may not be generalizable to all languages or working environments.

VII. RELATED WORKS

The impact of tangled changes has been reported in several contexts: The inspiring work by Herzig et al., [4], reported that at least 16.5% of all source files in the datasets they considered were incorrectly associated with bug reports when ignoring the existence of tangled change sets. In a large-scale study done at Microsoft on how developers understand code changes, Tao et al., reported that developers find it important for understanding to decompose changes into the individual development issues, but there is currently no tool support for that [6]. Bacchelli and Bird reported that tangled changes in code to be reviewed are often causing low quality reviews or longer time to review [7].

Herzig et al., were the first to implement an algorithm to automatically generate untangled commits given a tangled one. Their work greatly inspired our research. However, we see some limitations to their work that we explain in Section II: static-analyses dependency, incompleteness, and artificiality. The main differences with our work is that: (1) we count with fine-grained timing information of code changes as well as IDE events like test runs; (2) we work in a dynamically-typed language; (3) we evaluated our approach with developers.

Another source of inspiration comes from Robbes, who created a fine-grained change model of software evolution based on 3 principles [26]: (1) a program state needs to be represented accurately by an Abstract Syntax Tree (AST); (2) a program’s history is a sequence of changes, each one producing a program state (an AST) and changes can be composed into higher-level changes; (3) changes should be recorded by the IDE as they happen, not recovered from a VCS. Robbes et al., show how fine-grained change model can better detect logical coupling between classes [27]. Their paper presents new measures of logical coupling that we consider as a future extension of our voters.

Steinert et al., propose CoExist, an approach and associated tools to navigate the different states of a project based on its fine-grained changes [13]. CoExist’s tool suite allows for reverting any fine-grained change at the project level, comparing different states of a program, localizing the cause of a failing test in history, and reassembling changes to share untangled commits. Despite this large feature set, automatic clustering of dependent fine-grained changes to create untangled commits is left as future work. Our work can be seen as an extension of CoExist tool suite in this direction, despite its totally unrelated implementation.

Włok et al., presented a program analysis technique to identify commitable changes that can be released early, without causing failures of existing tests [28]. Włok remarks that an untangling algorithm would clearly benefit from having a model with a more accurate concept of change to add context information for individual change operations. Beyond our “Same Test Run” voter, we will leverage more the results of unit-test execution to cluster related changes.
VIII. CONCLUSION

Version control systems allow developers to control changes to source code, and enable understanding and analyses the evolution of software systems. Nevertheless, tangled commits make it harder to exploit the code change history.

In this paper, we devised and evaluated EpiceaUntangler, an approach whose ultimate goal is to help developers share self-contained changes that are well-decomposed into individual tasks. We build on the shoulders of others, and expand previous work by: (1) Working in an untyped language setting where static code analyses are more limited; (2) considering fine-grained code change information gathered during development; and (3) evaluating the resulting approach both on data generated by programmers who manually labeled it, and with programmers working on real-world development tasks.

Our results show that three features are especially important to perform clustering of fine-grained code changes: the time and the ordered distance between the changes, and whether the changed code belongs to the same class. Testing the features on historical data manually labeled by developers, we recorded good results (over 88% of accuracy in the worst case) in determining whether two changes should belong to the same cluster. When deploying the corresponding tool and approach with new developers, we recorded a median success rate of 91% and an average one of 75%.

Overall, this paper makes the following main contributions:

1) An analysis of the current points for improvement in the state of the art in untangling code changes.
2) A publicly available dataset of fine-grained code changes collected by recording the development sessions of two developers over the course of four months, and the corresponding manual clustering.
3) The creation of different features/voters and their evaluation, based on the aforementioned dataset, using machine learning approaches to model and classify pairs of fine-grained code changes, resulting in good accuracy results.
4) The creation of an approach and corresponding tool implementation, EpiceaUntangler, to untangle fine-grained code changes into clusters based on the three best voters and the best performing machine learning algorithm.
5) The deployment and evaluation of EpiceaUntangler with developers, who used it over the course of two weeks, resulting in good success rate scores.
